What are the Effects of Self-Assessment Preparation in a Middle School Science Classroom?

Sara E. Severance

Abstract. This research was conducted by an urban middle school science teacher who sought to investigate the effects of self-assessment on student performance. A group of students were asked to give themselves a score on each learning target assessed in class and to provide evidence for their decision. Student self-assessment scores were compared to scores given by the teacher to see if students who accurately assessed their own learning scored higher on final assessments than students who did not. Assessment scores between groups of students who completed the self-assessment preparation and students who did not were also analyzed. The data indicates no correlation between the ability to self-assess and achievement. However, further implications on self-assessment at the secondary level are discussed.

INTRODUCTION

This study aims to understand more about the effects of self-assessment in an urban middle school science classroom and provide more information about self-assessment accuracy at the secondary level. This study was conducted as part of the Streamline to Mastery professional development program.

Studies have shown that there are major benefits to student self-assessment [1]. Students who are able to self-assess become better critical thinkers and are more self-aware. It is believed that students who possess these skills are better able to direct their own learning and become more invested in their own education [1]. By teaching students to become more independent in their own learning and evaluation of learning, students will hopefully be able to transfer those skills to other areas of their life [2].

Additionally, students who are self-aware are more able to monitor their own progress. Self-assessment can help learners locate their strengths and weaknesses and get them to think about what they need to do in order to achieve at a higher level. This individual reflection helps students take ownership of their learning and become more pivotal advocates in their education, rather than just complacent receivers of knowledge [3].

Multiple studies have been done on self-assessment training at the university level. Falchikov and Boud [4] have done a complete analysis of self-assessment studies which included over fifty studies done in higher education. The individual studies compared self- and teacher marks and the closeness of those marks. The better-designed studies (according to Falchikov and Boud) produced higher closeness results as well as studies that involved students in advanced courses or graduate courses compared to introductory courses. Students in science also produced better closeness results compared to students in other disciplines.

Since the 1989 study, other higher education self-assessment studies have shown similar trends as well. McDonald [5] showed that students who received and practiced meta assessment training scored higher on both easy and difficult assignments than students who did not receive the training. Similarly, Etkina showed that students with higher conceptual gains reflected on their learning in a way that was more articulate and sophisticated [6]. In a longitudinal study, Chen [7] showed that university language students’ marks and comments became closer to their professor’s while using the same rubric over time.

While there is plenty of literature on self-assessment in higher education, my searches did not reveal many studies done at the secondary level, particularly the middle school level. Research implies that students as young as twelve can benefit from self-assessment and when trained can accurately self-assess with some level of sophistication [3]. Studies also show that self-assessment accuracy increases when clear descriptors are used, specific experiences are related, and functional skills are assessed rather than abstract ideas [8]. These are attributes of a middle school science class and shows that self-assessment can be done at this level.
METHODS AND DATA ANALYSIS

This study was conducted in an urban middle school science classroom during the 2010-2011 school year. Approximately 100 eighth-grade students were placed randomly in four sections of physical science with the exception of five special education students who were placed in the same section for ease of scheduling. During the first unit of study, students in the first section of science class received the self-assessment training and the other classes served as the control group. Throughout the course of the year, the treatment group changed so that each group received the treatment at least once, and then became part of the control group for the rest of the time.

The treatment group received the self-assessment training and used a self-assessment learning target tracker to record their thinking. The tracker was a 5-column graphic organizer that included sections for the date, learning target, self-assessment score, reason for the self-assessment score, and teacher score for each lesson. For the first lessons, the teacher modeled the correct way to fill in the self-assessment tracker and gave examples of specific vocabulary to use when explaining what the student does well with or what the student might struggle with. Students were given opportunities to discuss their ideas in pairs before writing. After modeling during the first few lessons, the teacher provided a structured time at the end of each lesson to discuss and fill in the self-assessment tracker. The trackers were collected at the end of the unit. Each activity or lesson took 1-3 class days to complete and for each activity there was a new corresponding learning target. Students in the control group used a different tracker that did not include a section for a self-assessment score or reason for the self-assessment score.

In the self-assessment tracker, the students assigned themselves a score for each learning target based on a 1-4 scale with 4 being the highest. These scores were later compared to the scores of the teacher, and a resulting discrepancy value was determined. We refer to a discrepancy value as the absolute value of the difference between the teacher score and student score. If a student did not complete an assessment question their score was omitted.

After the students reflected on their learning and completed the self-assessment tracker, the students completed and turned in an open-ended question that assessed the learning target for that lesson. The students received a score (1-4) from the teacher based on the specific rubric for that type of question. For example, if the question asked the student to analyze data, the “Analyzing Data” rubric was used. The rubrics used in this study correspond to the Science Education Public Understanding Program (SEPUP) which was the curriculum used in this middle school science classroom. All students received a copy of each of the types of rubrics used in class and student work examples were analyzed to help students understand what the language in each of the rubrics meant prior to writing their own response.

For this study both quantitative and qualitative data were collected. The quantitative data collected included scores reported by the students and teacher in the self-assessment trackers as well as survey data given at the end of each unit. I looked for a correlation between a students’ average discrepancy value and their final assessment score for that unit. I also looked for a correlation between discrepancy values and different types of questions being assessed.

Survey results were tallied and reported as percentages. The qualitative data from the students’ self-assessment trackers were analyzed by placing student rationales into two categories: students who used specific science vocabulary and students who did not use specific science vocabulary to explain their thinking.

RESULTS

There was no correlation between students’ discrepancy value and their scores on the final assessment ($r^2=0.0019$). Figure 1 shows a scatter plot of all the students in the treatment group. There is no pattern that shows students with low average absolute discrepancy values (better at self-assessing) scoring better on the final assessment than students with high absolute discrepancy values.

![Figure 1: Average Discrepancy Values compared to Test Scores](image)

The average scores for the treatment group showed no significant gains compared to the control groups. Figure 2 shows the average assessment scores for each section of students for each unit of study throughout the year. The section of students who received the self-assessment treatment switched for
each unit of study and this is indicated with the color black in Figure 2. The average assessment scores were more dependent on the class section rather than the treatment.

I hypothesized that students would get better at self-assessing over time. However, when looking at the data for treatment group one (which spanned the longest amount of time), the discrepancy scores did not get lower over a 10-week period of using the self-assessment trackers (see Table 1).

UC = Understanding Concepts, DI = Designing Investigations, AD = Analyzing Data, ET = Evidence and Trade-Offs

The type of the assessment question seemed to have more of an effect on the average discrepancy values for the first treatment group (N=23 students). Students were able to more accurately self-assess on questions that asked them to design an investigation or determine the evidence and trade-offs compared to analyzing data or explaining a specific concept (see Figure 3). Given that previous research on self-assessment has shown that students are likely to improve their closeness scores over time [7] and students who engage in self-assessment are more likely to score higher on assessments [5], I predicted that the data in this study would show similar results; it did not. This led me to investigate possible reasons as to why the self-assessment training did not have the effects I thought it would.

**CONCLUSIONS AND IMPLICATIONS**

First, I analyzed the survey results and found that 91% of students felt they were aware of their understanding or lack of understanding about a concept. Sixty-one percent of those students showed they could articulate their thinking using specific science vocabulary such as, “I do well writing procedures but I struggle with the independent and dependent variables.” This suggests that many of the students were able to write about what parts of a concept they felt confident in and what parts of a concept they struggled with, even if they were not able to correctly match their own numerical self-assessment score (1-4) with the score given by the teacher. If students showed their ability to articulate what they know and do not know, then why weren’t the assessment scores higher for those students?

I believe the missing piece is what the students do with this information. One hypothesis is that middle school students may not be ready to know what to do even when they know that they do not understand a concept. The self-assessment reflections took place at the end of a lesson which most of the time was at the end of a class period. Many students could accurately write about their understanding of the concept by the end of the lesson, but there were not structured in-class activities set up to help students move further in their understanding. So, students left class knowing what they understood or did not understand, but did not have a plan to address those needs.

Using the self-assessment tracker as a form of formative assessment can help students and teachers. A teacher’s ability to access students’ prior knowledge
and respond to the formative assessment in his or her classroom is an important factor in a student’s ability to learn a concept [9]. Using formative assessment tools makes students and teachers more aware of a student’s mastery of a concept. The awareness that comes from engaging in self-assessment can only improve concept attainment if that data is put into use and the student can learn whatever piece is still unclear. While thirteen and fourteen year-old students may have the ability to self-assess [3] they may not have the motivation or developmental capability to address those needs independently in order to influence assessment scores.

As a teacher in this middle school classroom, I would imbed a structured plan to address students’ needs on a more frequent basis. Often times, one day was taken out of the unit to differentiate for students before an assessment. This data shows that more frequent, even shorter sessions to address misunderstandings would be helpful for students.

Considerable time was spent with the students working with the rubrics and familiarizing students with the language, however it was clear that many students either lost the rubrics, or did not take time to reference them independently. Before each assessment was turned in, class time was given to review the rubrics but many students did not take advantage of this time. Either the students did not find this exercise useful or they were not concerned with their scores.

It would have been valuable to have pre-assessment data for students at the beginning of each unit of study. Next time, I would like students to see the learning targets ahead of time and give themselves a score and rationale for each target and then compare their responses after engaging in the lessons.

ACKNOWLEDGMENTS

I would like to thank Ryan O’Block, Valerie Otero and members of the Streamline to Mastery Program for their feedback and continued support. This work was partially funded by NSF grant DUE 937941.
